ABSTRACT Ab initio computation of molecular properties is one of the most promising applications of quantum computing. While this problem is widely believed to be intractable for classical computers, efficient quantum algorithms exist which have the potential to vastly accelerate research throughput in fields ranging from material science to drug discovery. Using a solid-state quantum register realized in a nitrogen-vacancy (NV) defect in diamond, we compute the bond dissociation curve of the minimal basis helium hydride cation, HeH⁺. Moreover, we report an energy uncertainty (given our model basis) of the order of 10⁻¹⁴ hartree, which is 10 orders of magnitude below the desired chemical precision. As NV centers in diamond provide a robust and straightforward platform for quantum information processing, our work provides an important step toward a fully scalable solid-state implementation of a quantum chemistry simulator.

ABSTRACT

Quantum simulation, as proposed by Feynman¹ and elaborated by Lloyd² and many others,³–⁷ exploits the inherent behavior of one quantum system as a resource to simulate another quantum system. Indeed, there have been several experimental demonstrations of quantum simulators in various architectures including quantum optics, trapped ions, and ultracold atoms.⁸ The importance of quantum simulators applied to electronic structure problems has been detailed in several recent review articles including refs 9–13 and promises a revolution in areas such as materials engineering, drug design, and the elucidation of biochemical processes.

The computational cost of solving the full Schrödinger equation of molecular systems using any known method on a classical computer scales exponentially with the number of atoms involved. However, it has been proposed that this calculation could be done efficiently on a quantum computer, with the cost scaling linearly in propagation time.⁶ There is now a growing body of theoretical work proposing efficient quantum simulations of chemical Hamiltonians, e.g., refs 14–24.

In contrast, experimental realizations of quantum simulations of quantum chemistry problems are still limited to small-scale demonstrations and are only performed in liquid-state NMR and photonic systems. First experiments demonstrated the simulation of the electronic structure of molecular hydrogen using quantum optics¹⁵ and liquid-state NMR.²⁵ Recently, the energy of another molecule, the helium hydride cation, was calculated in a photonic system using a quantum variational eigensolver algorithm.²⁶ Besides the electronic structure, simulation of chemical reaction dynamics on an eight-site lattice was performed in NMR.²⁷

Recently, the nitrogen-vacancy (NV) centers in diamond attracted significant attention due to its unique optical and spin...
properties. The NV center consists of a substantial nitrogen atom at the carbon site and an adjacent vacancy. Its negative charge state forms a spin triplet ground state, with \( m_s = 0 \) and \( m_s = \pm 1 \) sublevels that are separated by a zero-field splitting of \( D \approx 2.87 \) GHz. This spin system can be initialized and read out via optical pumping and spin-dependent fluorescence. The NV center therefore does not suffer from signal losses with increasing system size like NMR and avoids challenges such as the need for high-fidelity single-photon sources and detectors that are still beyond the present capabilities in optical quantum systems. Progress to date demonstrates that the NV centers are among the most accurate and most controllable candidates for quantum information processing. Milestone demonstrations include high-fidelity initialization and readout, heralded generation of entanglement, implementation of quantum control, ultralong spin coherence time, non-volatile memory, quantum error correction, as well as a host of metrology and sensing experiments. Several proposals to scale up the size of NV systems currently exist, e.g., refs 38 and 46. This makes the NV center an ideal candidate for a scalable quantum simulator.

Here, we demonstrate the quantum simulation of an electronic structure with the NV center at ambient conditions. We use a quantum phase estimation algorithm to enhance the simulations precision. Our experimentally computed energy agrees well with the corresponding classical calculations within chemical precision and a deviation of \( 1.4 \times 10^{-14} \) hartree. Furthermore, we obtain the molecular electronic potential energy surfaces by performing the simulation for different distances of the atoms.

RESULTS AND DISCUSSION

The chemical system we consider in this paper is the helium hydride cation, \( \text{HeH}^+ \) (Figure 1a), believed to be the first molecule in the early universe. While \( \text{HeH}^+ \) is isoelectronic (i.e., has the same number of electrons) with the previously studied molecular hydrogen, the reduced symmetry requires that we simulate larger subspaces of the full configuration interaction (FCI) Hamiltonian \( H_{\text{sim}} \). Specifically, we consider

\[
H_{\text{sim}} = T_e + W_{ee} + V_{en}(R) + E_N(R) \quad (1)
\]

in a minimal single particle basis with one site per atom. Here, \( T_e \) and \( W_{ee} \) are the kinetic and Coulomb operators for the electrons, \( V_{en} \) is the electron–nuclear interaction, and \( E_N \) is the nuclear energy due to the Coulomb interaction between the hydrogen and the helium atom. The last two terms depend on the internuclear distance \( R \).

In this work, we consider the singlet \( (S = 0) \) sector of the electronic Hamiltonian in a minimal single-electron basis consisting of a single site at each atom given by contracted Gaussian orbitals. After taking symmetries into account, the Hamiltonian can be represented as a \( 3 \times 3 \) matrix in the basis \( |\Psi_1, \Psi_0, \Psi_1, \Psi_0, \Psi_1, \Psi_0, \Psi_1, \Psi_0, \Psi_1, \Psi_0\rangle \). Each term of the Hamiltonian in the single particle basis \( \langle \chi_e | (T_e + V_{en}) | \chi_e \rangle \) is precomputed classically at each internuclear separation \( R \) using the canonical spin orbitals found via the Hartree–Fock (HF) procedure which often scales as a third order polynomial in the number of basis functions.

After obtaining \( H_{\text{sim}} \) through this (typically) efficient classical computation, we perform the quantum simulation of this molecule on a single-NV register, which consists of an electronic spin-1 and an associated \(^{14}\text{N} \) nuclear spin-1 forming a qutrit pair (Figure 1b). The electronic spin-1 of the NV system acts as the simulation register through mapping the molecular basis \( |\Psi_1, \Psi_0, \Psi_1, \Psi_0, \Psi_1, \Psi_0\rangle \) onto its \( m_s = (1, 0, -1) \) states. Such a compact mapping is more efficient in that the states of simulated system and of the simulation system are simply enumerated and equated. The \(^{14}\text{N} \) nuclear spin-1 is used as the probe register to read out the energies using the iterative phase estimation algorithm (IPEA), as shown in Figure 1c. The simulation is realized by three steps: (i) preparation of the system into an ansatz state \( |\psi_i\rangle \), which is close to an eigenstate of the simulated Hamiltonian \( H_{\text{sim}} \); (ii) evolution of the simulation register under the molecular Hamiltonian \( H_{\text{sim}} \) to generate phase shift on the probe register; and (iii) readout of the phase shift on the probe register to extract the molecular energy (Figure 2a).
In the first step, an ansatz state is prepared that has an overlap with the corresponding eigenstate $|e_k\rangle$ that decreases at most polynomially as the system size grows. The phase estimation algorithm\textsuperscript{40} can then be used to project the ansatz state into the exact eigenstate with sufficiently high probability. One possible approach to realize this requirement is to use adiabatic state preparation,\textsuperscript{14,25,50} the performance of which depends on the energy gap during the entire evolution process. An alternative approach is to approximate the eigenstate with a trial state. In our demonstration, the simulation register is initialized in a trial state $|\psi(0)\rangle = (|0\rangle + |\pm 1\rangle)\sqrt{2}/2$ through a $\pi/2$ pulse to obtain a phase shift in the evolution. In the next step, a controlled-$U(t)$ gate for different times $t$, where $U(t) = \exp(-i H_{\text{sim}} t)$, is applied on the simulation register to encode the energies into a relative phase of the probe register, resulting in the state

$$|\psi(t)\rangle = \frac{1}{\sqrt{2}} \sum_k a_k (|0\rangle + e^{-i \delta_k t} | -1\rangle)|e_k\rangle$$  

where the trial state is expressible as a superposition of all the $H_{\text{sim}}$ eigenstates $|\psi\rangle = \sum a_k |e_k\rangle$. The reduced density matrix of the probe register

$$\rho_{\text{probe}}(t) = \frac{1}{2} \left( \sum_k |a_k|^2 e^{-i \delta_k t} \right)$$

obtains a phase shift (off-diagonal elements) that contains the information about the energies. Finally, the phase information is transferred to the electron spin for readout by a nuclear spin $\pi/2$-pulse, followed immediately by selective $\pi$-pulses on the electron spin. To measure the energy precisely, we perform a classical Fourier analysis on the signal for different evolution times ($t_s, 2t_s, \ldots, Lt_s$). This readout method can help to resolve the probability $|a_k|^2$ of each eigenstate $|e_k\rangle$ and approximate the corresponding energy $E_k$. We choose $t_s$ such that the sampling rate $1/t_s > |E_k|/\pi$. An example for the experimental Fourier spectrum is shown in Figure 2b. The position of the peak indicates the eigenvalue of the molecular Hamiltonian.

To enhance the precision of the energy eigenvalues, an iterative phase estimation algorithm is performed. A central feature of this algorithm includes repeating the unitary operator $U$ to increase readout precision. Expressing the energy as a string of decimal digits, $E_k = x_1, x_2, x_3 \ldots$, the first digit $x_1$ can be determined by the

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure2}
\caption{Energy readout through quantum phase estimation algorithm. (a) Experimental implementation of the IPEA algorithm. The controlled gate $U'$ is realized using optimal control. The $x, y$ phases in the last $\pi/2$ pulse measure the real and imaginary parts of the signal, respectively, which yield the sign of the measured energy. The number of repetitions $N = 10^{k-1}$ depends on the iteration $k$. (b) Experimental results of iterative phase estimation algorithm to enhance the precision of measured energy for the case of $R = 90$ pm. The Fourier spectrum of the first iteration ($k = 1$) fixes the energy roughly between $-10$ and $0$ hartree. The precision is then improved iteratively by narrowing down the energy range. In each iteration, the energy range is divided into 10 equal segments. The red area indicates the energy range for the next iteration. After each iteration at least one decimal digit, denoted by the number in the red area, is resolved. Note that the value here is offset by $tr(H_{\text{sim}}) / 3$ (see the Supporting Information for details). (c) The uncertainty of the measured energy as a function of the iteration number.}
\end{figure}
first-round phase estimation process. Once $x_1$ is known, the second digit $x_2$ can be iteratively determined by implementing the unitary operator $U^p$, where $p = 10$. For the $k^{th}$ iteration, $p = 10^{k-1}$. An increasingly precise energy can be obtained through continued iterations. However, in practice, the repetitions and therefore the iterations are fundamentally limited by the coherence time of the quantum system. Moreover, the accumulated gate errors become a dominant limitation of the energy precision as the repetitions increase. To avoid such shortcomings, in our demonstration the time evolution operators $U^p$ are realized and optimized with optimal control theory, which can overcome several difficult features found when scaling up the register size. Although it cannot be applied in large registers to generate the quantum gates directly, it can be used to generate flexible smaller building blocks, ensuring high-fidelity control in future large-scale applications. In the present case, the method is unscalable because we compute the unitary propagator using a classical computer. However, by using a Trotter-type gate sequence to implement the propagators, e.g., this can be designed with polynomially scaling.

Figure 2b,c show the results of such an iterative process in the case of internuclear distance $R = 90$ pm with trial state $|+1\rangle$. As the iterations increase, more precise decimal digits of the ground-state energy are resolved. After 13 repetitions, the molecular energy, with an offset $\text{tr}(H_{\text{sim}})/3$, is extracted to be $-1.020170538763387 \pm 8 \times 10^{-15}$ hartree, very close to the theoretical value, which is $-1.020170538763381$ hartree, with an uncertainty of $\pm 1.4 \times 10^{-14}$ hartree. To the best of knowledge, our results are four times more accurate than the previous record.

Once the energies have been measured, we can obtain the potential energy surface of the molecule by repeating the procedure for different distances $R$ (Figure 3). The ground-state energy surface is obtained with the trial state $|+1\rangle$, and the first excited state energy surface is obtained with the trial state $|-1\rangle$. We obtain the remaining eigenenergy (of the second excited state) without further measurement by subtracting the ground and first excited-state energies from the trace of $H_{\text{sim}}$. The potential energy surfaces can be used to compute key molecular properties such as ionization energies and vibrational energy levels. An important example is the equilibrium geometry: we found the minimal energy for the ground state, $-2.86269$ hartree, at a bond length of 91.3 pm. In addition, we obtained a binding energy of 0.07738 hartree in our basis.

To improve the accuracy of our results we would need to simulate the system in a larger basis. Recent advances in this direction show that we can enlarge the size of the NV spin system by either including more coupled nuclear spins associated with single NV electron spin or correlating several electron spins mediated through optical photons or through magnetic interactions between them. The former method is able to provide ~6 nuclear spins for single NV node, and the latter method currently is limited to two electron spins. In both hybrid-spin systems the control is shown to be universal. Combining these two methods in principle could enlarge the NV system to a 10-qubit quantum processor which is enough to perform more complicated tasks. In these large systems, the simulated propagators can be implemented using Trotter sequences and should be accompanied by error correction. Optimal control methods, as we have demonstrated here, should prove necessary to perform these tasks with satisfactory precision.

**CONCLUSION**

We have demonstrated the most precise quantum simulation of molecular energies to date, which represents an important step toward the advanced level of control required by future quantum simulators that will outperform classical methods. The energies we obtained for the helium hydride cation surpass chemical precision by 10 orders of magnitude (with respect to the basis). The accuracy of our results can be increased by using a larger, more flexible single-particle basis set, but this will require a larger quantum simulator that eventually will require error correction schemes.

---

Figure 3. Energy surfaces of the HeH$^+$ molecule. The energy surface of the second excited state can be obtained by subtracting energies of the ground and first excited states from the trace of $H_{\text{sim}}$ and is not shown. All of the measured energies are obtained in five iterations.
Our study presents evidence that quantum simulators can be controlled well enough to recover increasingly precise data. The availability of highly accurate energy eigenvalues of large molecules is presently far out of reach of existing computational technology, and quantum simulation could open the door to a vast range of new technological applications. The approach we took was based on iterative phase estimation and optimal control decompositions—their combinations for building blocks for any solid-state quantum simulator. Even more generally, this study would suggest that the techniques presented here should be employed in any future simulator that will outperform classical simulations of electronic structure calculations.

**METHODS.**

Computation of Molecular Hamiltonians. The full configuration interaction Hamiltonian is a sparse matrix, and each matrix element can be computed in polynomial time. The N-electron Hamiltonian is asymptotically sparse. For a basis set with \( M \) orbitals, there are \( M^N \) terms in the Hamiltonian but the Hamiltonian is of size \((N!)/(M!(N-M)!)\) ∼ \(M^N\) which is exponential as the number of electrons grows. To generate the Hamiltonian, we fix the nuclear configuration and then compute the corresponding Hamiltonian, we fix the nuclear configuration and then compute the necessary one- and two-body integrals which parametrize the FCI matrix at each fixed bond length in the standard STO-3G basis. Using the PSI3 electronic structure package. The minimal basis HeH⁺ system has two spatial orbitals which we denote as \( g(r) \) and \( h(r) \) and two spin functions denoted as \( \alpha(\sigma) \) and \( \beta(\sigma) \) which are eigenstates of the \( S_z \) operator. We combine these to form four spin orbitals, \( χ_1 = g(r)\alpha(h) \), \( χ_2 = g(r)\beta(h) \), \( χ_3 = \alpha(h)\alpha(h) \), and \( χ_4 = \beta(h)\beta(h) \). There are six possible two-electron Slater determinants, \( \Psi_1 = \langle χ_1|χ_2⟩ \), \( \Psi_2 = \langle χ_1|χ_3⟩ \), \( \Psi_3 = \langle χ_1|χ_4⟩ \), \( \Psi_4 = \langle χ_2|χ_3⟩ \), \( \Psi_5 = \langle χ_2|χ_4⟩ \), and \( \Psi_6 = \langle χ_3|χ_4⟩ \). More explicitly

\[
\Psi_i = \frac{1}{\sqrt{2}} \left[ \chi_{1}\sigma_{i} \chi_{2}\sigma_{i} \right] \quad i = 1, 2, \ldots, 6
\]

States \( \Psi_1, \Psi_2, \Psi_4, \) and \( \Psi_5 \) have total projected spin of \( M_s = 0 \), whereas \( \Psi_3 \) and \( \Psi_6 \) have projected values of \( M_s = 1 \) and \( M_s = -1 \) respectively. Only \( \Psi_1 \) and \( \Psi_2 \) are valid eigenstates of the total spin operator \( S_z \); however, the symmetric and antisymmetric combinations of \( \Psi_3 \) and \( \Psi_4 \) yield the \( m_s = 0 \) triplet and an additional singlet, respectively. When a computation is requested on the singlet state, the PSI3 package computes the symmetry-adapted FCI matrix in the basis of \( \Psi_1, \Psi_2, \Psi_4, \) and \( \Psi_5 \). By combining \( \Psi_1 \) and \( \Psi_2 \) we obtain the three \( \text{HeH}^+ \) singlet states used in this experiment: \( \Psi_1, \Psi_2, \) and \( \frac{1}{\sqrt{2}}(\Psi_4 - \Psi_5) \).

**Sample Characteristics.** We use a NV in high-purity diamond grown by microwave-assisted chemical vapor deposition (CVD). The intrinsic nitrogen content of the grown crystal is below 1 ppb, and the C=C content is enriched to 99.9%. Experiments are performed at room temperature with an applied magnetic field of 11 G. The electron spin’s coherence times are \( T_2 \approx 80 \) μs and \( T_2^* \approx 600 \) μs, while the nuclear spin’s coherence time is limited by the relaxation time of the electron spin (on the order of milliseconds).

**Controlled U(t’S)** Gate Realization. To calculate \( U(t'S) \), we use the gradient ascent pulse engineering (GRAPE) algorithm to optimize the pulse sequence, with the final fidelity always larger than 0.99. For every controlled gate, the pulse sequence consists of 10 pieces of 140 ns each. Two microwave frequencies are applied simultaneously to control the electron spin, in the observed hyperfine peaks of the \( |m_s = -1, m_I = 0⟩ \) and \( |m_s = 1, m_I = 0⟩ \) transitions.
